Abstract
Being a staple food crop, the potato provide basic nutrition to many people and offer several nutritional benefits. Despite valued as carbohydrate source, tubers with higher levels of bioactive compounds (as vitamin C) could have a positive impact on the people health. The goal of this research was to evaluate the behavior of 10 potato varieties with different L ascorbic acid content after inoculation with potato virus Y (necrotic strains). Another goal of this study was to elucidate the biochemical basis responsible for different reaction to infection with potato virus Y necrotic strains PVY\textsuperscript{N} among several varieties which differ in their susceptibility or resistance to this pathogen.

The potato varieties, including new Romanian and commercial cultivars evaluated for L ascorbic acid content, were the following: Christian, Roclas, Red Lady, Marvis, Castrum, Brasovia, Hermes, Sante, Riviera and Carrera. The vitamin C content was estimated using an enzymatic method (L-ascorbic test kit, Megazyme Ltd., Bioreba).

The L ascorbic acid content was analyzed in the flesh only, with variety Hermes showing the highest content (746 mg/kg\textsuperscript{1} DW) in tubers after inoculation. Significant differences in vitamin C content were observed across the cultivars before and after virus inoculation. Excepting the cultivars Christian, Riviera and Sante, which were very resistant and resistant to mechanical inoculation, all the other varieties presented 48.6 - 100% infected plants. After 3 months from harvesting, the frequency of tubers with symptoms was between 8.2 - 34.7% for varieties Roclas, Marvis, Castrum, Brasovia and for Red Lady, Carrera, Hermes varieties this percentage was higher (69.2-98.2%).

This study provides information on level of important micronutrients as L ascorbic acid in a range of several health and PVY\textsuperscript{N} infected potato cultivars.

Key words: Potato, L ascorbic acid, Potato Virus Y, Necrotic strains.

1. Introduction
For solving food shortages at the beginning of this millennium, the potato proves to be a product with promising perspectives. Considered by some a common product, cheap food, poor people’s food and the plant of poor areas, the potato is actually a product that helps improving the daily diet being rich in carbohydrates, vitamins and minerals. For Romania, the potato is a strategic food, contributing to the national food safety system. Our country is ranked on the third position in Europe in terms of area cultivated with potatoes (after Poland and Germany) [1]. Potato is the third most consumed food, after rice and maize [2], and their tubers are recognized as a good source of: carbohydrates, vitamin B1, B3 and B6, potassium, phosphorus and magnesium. It has a moderate content of iron, but its high L ascorbic acid levels promote iron absorption. Potato is rich in essential amino acids. It also contains pantothenic acid, folate and riboflavin [3]. While 50 years ago more than half of the global annual production output was concentrated in Russia,
Poland and Germany, and now, around 40% comes from China, India and Russia. China and India have seen a dramatic increase, with both countries doubling their production in the last 20 years [2]. This makes potato an important commodity in Asian developing countries, with the added advantage that food security is augmented as compared to other staple crops because potatoes are only marginally traded in international markets, making them less susceptible to price volatility.

Vitamin C is the most abundant vitamin in potato and it is estimated that about 18% of the recommended daily allowance (RDA) of vitamin C in Australia and 21% in the UK are provided by potatoes [3, 4, 5, and 6]. Three main biological functions have been identified for L ascorbic acid: enzyme cofactor, free radical scavenger and donor/acceptor of electrons at the plasma membrane. Humans have lose ability to synthesize L ascorbic acid and depend on the diet to acquire the necessary amounts required to maintain good health. Deficiency of the vitamin C cause the disease scurvy characterized by spots on the skin, spongy gums and bleeding from mucous membranes. Is caused by deficient synthesis of collagen in which L ascorbic acid is cofactor [3, 6, and 7]. Although, nowadays, scurvy is considered rare in developed nations, the vitamin C intake of significant part of the population of some of these countries may be below recommended daily intake - RDA (80 mg per day in European Union EC) [8]. About 13% of the population in the USA or 1 in 7 young adults in Canada have been reported to be deficient in vitamin C with certain groups such as smokers, pregnant women and people of low socioeconomic status at a higher risk of deficiency is common, L ascorbic acid is particular important because it can reduce the chelating effect that compound phytic acid has on iron, increasing its bioavailability [3].

Distributed worldwide, potato virus Y (PVY, potyvirus genus, family Potyviridae) is a major economic disease agent for the crops. This pathogen causes losses in solanaceous crops such potato (Solanum tuberosum), tobacco (Nicotiana tabacum) and tomato (Lycopersicum esculentum) [9]. PVY in potato received (in the last period) a special attention because this pathogen is one of the most economically important problems in seed potatoes in the world. This virus is responsible for serious decreases yield and quality tubers, but the main problem in seed potato production is the requirement for a strict PVY tolerance limits for certified lot of seed. High levels of PVY are responsible for the rejection of many seed potato lots. Also, a significant reduction of the crop value was noticed and in a certified seed’s shortage, too, especially for certain varieties highly susceptible to PVY infection [10, 11, 12, 13].

In the last three decades new PVY strains have emerged, some of them (e.g. PVY \(N^{\text{N}}\)) induce barely visible symptoms during the growing season (often being unnoticed during visual inspection) and others (e.g. PVY \(N^{\text{NN}}\)) produce symptoms on tubers, causing the so-called the necrotic ring staining of tubers. Due to the fact that these viral strains may affect the resistance of some potato varieties compared to other strains of the virus Y (PV\(Y^\text{N}\) and PV\(Y^\text{N}\)) numerous varieties that were considered resistant passed into the category of sensitive ones, which affected the production of the potato in our country. The damage caused by this pathogen agent is both quantitative (significant reduction of production) and qualitative (commercial depreciation of tubers). In case of cultivation of sensitive varieties under favourable conditions, financial losses can be important both for potato consumption (it can become unmarketable) as for seed potatoes (it will be downgraded or rejected from certification). PV\(Y^{\text{NN}}\) strains produce symptoms on tubers, causing the so-called necrotic ring staining of tuber (PNRTD). Being very aggressive, these strains can overcome existing resistance to infection with other strains of potato virus Y (PV\(Y^\text{N}\) and PV\(Y^\text{N}\)) [9, 14, 15].

The aim of this study was to quantify the levels of L ascorbic acid in 10 potato varieties with different L ascorbic acid content before and after inoculation with potato virus Y necrotic strains (PV\(Y^\text{N}\)). Another goal of this study was to elucidate the biochemical basis responsible for different reaction to infection with potato virus Y among several varieties which differ in their susceptibility or resistance to this pathogen.

Potato with high increase content of vitamin C could have an important impact on human health, especially in populations where potato is the main staple food crop and therefore, would be of interest to consumers, producers and policymakers.

2. Material and Methods

2.1 Biological material

Ten potato varieties were chosen for this study. The biological material included:

- Economically important commercial cultivars such as: Riviera, Carrera, Red Lady, Hermes and Sante which represented about 40% of the production area in Romania in 2015 [16].
- Christian and Roclas cultivars, Romanian varieties very appreciated in Romania for their nutritional quality.
- Sarmis, Marvis, Castrum, Brasovia (new Romanian varieties).

The health tubers were obtained from the Department of Breeding and Seed Production, National Institute of Research and Development for Potato and Sugar Beet Brasov (NIRDPSB Bv).

From each variety, 6 pots (with 1 eye pieces) in three repetitions were planted. Plants were grown in 18 cm
pots in green house conditions. After emergence, plants have been mechanical inoculated, using a PVY<sup>0</sup> source (secondary infection Record variety). After the inoculation, disease symptoms were observed and ELISA tests have been made, in the aim to confirm the infection. At harvesting, we select 2 tubers from each pot and there were tested 3 samples (4 tubers/samples) for each variety. The other tubers were keep and the percentage of tubers with necrotic symptoms was estimated at harvesting time and later (after 3 months storage at 4 - 8 °C).

### 2.2 Detection of PVY<sup>0</sup> infections

The analysis was performed following the protocol Clark and Adams (1977) [17]. Rinsed microplates filled with substrate solution (p-nitro-phenyl-phosphate) were incubated one hour and the absorbance values were estimated at 405 nm (A<sub>405</sub>) using a Tecan SunRise reader (software Magellan).

In the first stage, the material was tested for Potato virus Y (polyclonal antibodies) and only the PVY infected material was keepped, to identify the samples infected with necrotic strains (PVY<sup>0</sup>). This biological material was retested with monoclonal antibodies (mAb) or polyclonal (PCA).

The microplates were coated with anti PVY-NOC mAb (Bioreba, Switzerland, antibodies that could recognize all the PVY strains excepting the PVY<sup>0</sup>) and the virus was detected using alcalin phosphatase (AP) linked to anti–PVY-NOC mAb (Bioreba, Switzerland, specific for the strains PVY<sup>0</sup>).

### 2.3 Sample preparation

For the healthy material, composite samples were prepared by pooling tubers. Tubers were peeled with a potato peeler, the flesh of each tuber quartered from stem to bud and one of the quarters sliced. Flesh tissues were freeze-dried, grounded to a fine powder (using a coffee grinder) and stored to -20 °C until analysis.

### 2.4 Vitamin C analysis

Dry matter (thermoventilated oven at 105 °C), vitamin C (a spectrophotometric method, L ascorbic acid test kit, Megazyme, Bioreba) were determined on healthy tubers before planting them in the pots. We choosed a representative sample of tubers per plot. The sample for these analysis were choosed from each 2 tubers (2 tubers/sample). The characteristics determination was made in 3 repetitions [18].

### 2.5 Statistical interpretation

Each set of comparable assay was conducted at the same time and with the same bulk sample. Analysis of variance (ANOVA) and Duncan’s multiple range test were used to analyze the data.

3. Results and Discussions

After the inoculation, about half of plants presented mosaic symptoms on leaves (Carrera, Red Lady and Hermes) or with necrosis on leaves, veins, petioles and stems followed by wilting of leaves (Marvis, Castrum). The first foliar symptoms from primary infections on the leaves have been observed on Hermes, Carrera and Red Lady varieties and later on cv. Castrum and Marvis. In several plants, the virus began to multiply in the leaves six days after PVY<sup>0</sup> inoculation. As we signaled in other paper [18], simultaneously, the virus spread to the stem, followed by the upper, green parts of the plants. In this way, the virus multiplied vigorously in the potato variety Carrera and Red Lady. Similar phenomena observed to the extremely susceptible variety Hermes, and the percentage of infected plants being maximal in these situations. As waited, the virus did not multiply in the cultivars Riviera, Sante and Christian. Excepting these three cultivars, which were very resistant and resistant to mechanical inoculation, all the other varieties presented 44.4 - 100% infected plants. After 3 months from harvesting, the frequency of tubers with symptoms was between 8.2 - 34.7% for varieties Roclas, Brasovia, Marvis, Castrum and for Red Lady, Carrera, Hermes cultivars this percentage was higher (69.2 - 98.2%) (Table 1).

* Data represents the mean values (3 repetitions; 6 pots for each repetition) ± standard deviation.
** ELISA test made after 4 weeks after inoculation (for identify PVY<sup>0</sup> infected plants).
*** Tuber symptoms characterized by raised or sunken necrotic lesions, were scored at harvest and after 3 months storage at 4 - 8 °C.

The vitamin C percentages (% from dry matter) of tubers planting in the pots were very different. As shown in Table 2, these values were significantly low to the varieties resistant and very resistant to the inoculation like cv. Riviera, Christian and Sante compared with the sensible cultivars Hermes, Carrera and Red Lady.
The simple correlation coefficient Pearson revealed significantly higher values regarding the vitamin C content (as compared to the percent of infected material for the most resistsent potato varieties) both in healthy tubers (before virus inoculation) and in tubers harvested from PVY\textsuperscript{N} inoculated plants (Table 3).

As shown in Figure 1 (A & B), there is a correlation between the vitamin C content of tubers planted in the pots and the behaviour of inoculated material. So, the variants which started in vegetation with low percentage of vitamin C were resistant to the PVY\textsuperscript{N} inoculation (Riveria, Christian, Sante, Roclas, Brasovia).

Concerning these cultivars, the percentage of tubers with necrotic symptoms visible immediately after harvesting and after 3 months from the harvest was 0.0%.

The variants which started in vegetation with high content of vitamin C were sensible to the virus inoculation (Hermes, Red Lady and Carrera) (Figure 1 A & B).

In our study, the total vitamin C content in the flesh tissues were investigated in 10 varieties of potato grown under uniform greenhouse cultural conditions. Values reported for this compound contents were, in general, lower to those found in the literature [19, 20, 21, and 22] maybe because of the cultural conditions, especially the soil composition. A previous study also found higher ascorbic acid levels in potatoes grown in basic soil [23]. Significant differences were seen between varieties vitamin C content and for behavior to PVY\textsuperscript{N} inoculation (necrotic symptoms on the tubers at harvest and on the material stored 3 months at 4 - 8 °C).

**4. Conclusions**

- The variety and the vitamin C content (% dry weight) of tubers used for the experiment influenced the behaviour of the material after the inoculation with potato virus Y (Y\textsuperscript{n} strain- variety Record).
- Excepting the cultivars Riviera, Sante and Christian, which were very resistant and resistant to mechanical inoculation all the other varieties presented 44.44 - 100% infected plants. At harvesting, the necrotic symptoms could be noticed on the tubers from all the other varieties, excepting the cv. Riviera, Sante, Christian, Roclas and Brasovia. Regarding the other varieties, the evolution of symptoms on tubers is going on immediately after harvesting.
- After 3 months from harvesting the inoculated material, the frequency of tubers with symptoms was between 8.2 - 34.7% for varieties Roclas, Marvis, Castrum, Brasovia and for cv. Carrera, Red Lady and Hermes this percentage was very high (69.2 - 98.2%).
- The samples with significantly lower vitamin C content (cv. Carrera, Sante and Christian) were resistant to PVY\textsuperscript{n} inoculation. Thus, after 3 months from harvest, the stored tubers didn’t have visible tuber necrotic disease symptoms.
- Results of this study show a significant difference between the total vitamin C content of the healthy and PVY\textsuperscript{n} infected tubers from the varieties tested (cultivars with different behaviour to inoculation with necrotic strain of potato virus Y). However, it must be considered that the results presented in this paper arise from working with only a few of biological material and upper greenhouse growing conditions. Also, extended field trials would be made to confirm our research results in fields conditions.
